Article abstract

In order to evaluate the late-stage physical and chemical evolution of the Upper Devonian, peraluminous South Mountain Batholith, mineral chemistry (muscovite, feldspars), oxygen isotopes (whole rock, mineral separates) and Al/Si ordering of K-feldspar have been investigated. Muscovite, K-feldspar and albite define coherent chemical trends with respect to compatible (Ba, Sr, Eu) and incompatible (Li, Cs, Rb) elements such that crystal fractionation processes are reflected. However, the influence of a fluid phase is seen in terms of Eu/Eu* of greisen muscovite and the light REE profiles (chondritic) of chemically evolved K-feldspar. The dominance of monoclinic K-feldspar, even in pegmatitic environments, indicates that either single or multiple processes impeded Al/Si ordering (e.g., cooling rate, fluid and/or rock composition). However, locally the development of triclinic K-feldspar dominates where intense fluid-rock interaction occurred (e.g., greisens), thus reflecting alteration at temperatures $\leq 450^{\circ}\text{C}$. $\delta^{18}\text{O}$ values of minerals from pegmatites reflect disequilibrium conditions related to variable degrees of fluid-rock interaction after crystallization. Calculated $\delta^{18}\text{O}_{\text{IMi}}$ (mostly 5–10 ‰) indicates a dominantly magmatic fluid reservoir, both ^{18}O -enriched (to +18 ‰) and ^{18}O -depleted (to < -4 ‰) fluids infiltrated the system, indicating that local fluid mixing occurred.

In order to evaluate the late-stage physical and chemical evolution of the Upper Devonian, peraluminous South Mountain Batholith, mineral chemistry (muscovite, feldspars), oxygen isotopes (whole rock, mineral separates) and Al/Si ordering of K-feldspar have been investigated. Muscovite, K-feldspar and albite define coherent chemical trends with respect to compatible (Ba, Sr, Eu) and incompatible (Li, Cs, Rb) elements such that crystal fractionation processes are reflected. However, the influence of a fluid phase is seen in terms of Eu/Eu* of greisen muscovite and the light REE profiles (chondritic) of chemically evolved K-feldspar. The dominance of monoclinic K-feldspar, even in pegmatitic environments, indicates that either single or multiple processes impeded Al/Si ordering (e.g., cooling rate, fluid and/or rock composition). However, locally the development of triclinic K-feldspar dominates where intense fluid-rock interaction occurred (e.g., greisens), thus reflecting alteration at temperatures $\leq 450^\circ\text{C}$. $\delta^{18}\text{O}$ values of minerals from pegmatites reflect disequilibrium conditions related to variable degrees of fluid-rock interaction after crystallization. Calculated $\delta^{18}\text{O}_{\text{fluid}}$ (mostly 5-10 ‰) indicates a dominantly magmatic fluid reservoir; both ^{18}O -enriched (to +18 ‰) and -depleted (to $<+4$ ‰) fluids infiltrated the system, indicating that local fluid mixing occurred.

Dans le but d'évaluer l'évolution physique et chimique dans ses derniers stades du batholite péralumineux dévonien supérieur de South Mountain, on a étudié la chimie des minéraux (muscovite, feldspaths), les isotopes de l'oxygène (sur roche totale et sur fractions monominérales) et l'ordonnance Al/Si au sein des feldspaths potassiques. La muscovite, le feldspath potassique et l'albite déterminent des tendances chimiques cohérentes vis-à-vis des éléments compatibles (Ba, Sr, Eu) et incompatibles (Li, Cs, Rb), de façon telle qu'elles reflètent des processus de cristallisation fractionnée. Cependant, l'influence d'une phase fluide s'exprime en termes du rapport Eu/Eu* des muscovites dans les greisens et des profils (chondritiques) des T.R. légères de feldspaths potassiques ayant subi une évolution chimique. La dominance du feldspath potassique monoclinique, même dans les environnements pegmatitiques, indique qu'un ou plusieurs processus firent entrave à l'ordonnance Al/Si (e.g., taux de refroidissement, composition du fluide et/ou de la roche). Cependant, d'une façon locale, le développement de feldspath potassique triclinique domine là où l'interaction entre le fluide et la roche fut intense (e.g., dans les greisens), reflétant ainsi une altération à des températures atteignant 450°C . Le dosage $\delta^{18}\text{O}$ des minéraux prélevés dans les pegmatites reflète des conditions de déséquilibre reliées à divers degrés d'interaction entre le fluide et la roche après leur cristallisation. La valeur calculée $\delta^{18}\text{O}_{\text{fluide}}$ (pour la plupart 5-10 ‰) indique un réservoir de fluide à dominance magmatique; le système fut infiltré par des fluides aussi bien enrichis (jusqu'à +18 ‰) qu'appauvris (jusqu'à $<+4$ ‰), ce qui indique qu'un mélange de fluides se produisit à l'échelle locale.

INTRODUCTION

The role of fluids during the terminal stages of intrusion, solidification and cooling of igneous complexes has been examined over the past few decades by, among others, H.P. Taylor and coworkers (summaries in Taylor, 1968, 1978, 1988; Taylor and Sheppard, 1986). These investigators have demonstrated the variety of source reservoirs for fluids and the influence they have in terms of isotopic equilibria among the mineral constituents. The fact that fluids played a role in the late-stage evolution of the Upper Devonian, peraluminous South Mountain Batholith of Nova Scotia (Fig. 1) is indicated by the presence of locally abundant pegmatites, variable types of alteration (cf. Charest, 1976; Charest *et al.*, 1985; Corey, 1988; Kontak and Corey, 1988; Logothetis, 1985) and local concentrations of granitophile elements in mineralized pegmatites and greisens (cf. Chatterjee *et al.*, 1985a, 1985b; Chatterjee and Strong, 1984; O'Reilly *et al.*, 1982).

In an earlier paper, Kontak *et al.* (1988) discussed the geochemical and oxygen isotopic evolution of the South Mountain Batholith using a suite of samples that is representative of its

progression from the early to late stages of differentiation. Continuity of whole-rock geochemical trends for granodiorite through late-stage leucogranite units was interpreted to reflect the dominance of crystal-melt equilibria during progressive fractional crystallization involving the major silicate phases and accessory minerals (see also Longstaffe *et al.*, 1980). However, more evolved leucogranites (designated leucogranites II; Kontak *et al.*, 1988) associated with pegmatite occurrences were found to have chemical signatures, particularly in their rare-earth-element (REE) patterns, indicative of a relatively more important role of fluid equilibria in their evolution. Whole-rock oxygen isotopic data were found to indicate a uniform composition for the granites of ca. 10.6 ± 0.5 ‰ (n=14), regardless of proximity to the contact with sedimentary rocks of the flyschoid Meguma Group or degree of differentiation (e.g., K/Rb or wt. % SiO₂). However, disequilibrium oxygen isotope fractionation between quartz and feldspar in pegmatites was interpreted to indicate variable re-equilibration with mostly late-stage, cooling magmatic fluids. There was some suggestion, however, that additional fluids of metamorphic and meteoric origin were also involved in the late-stage evolution of the batholith. For example,

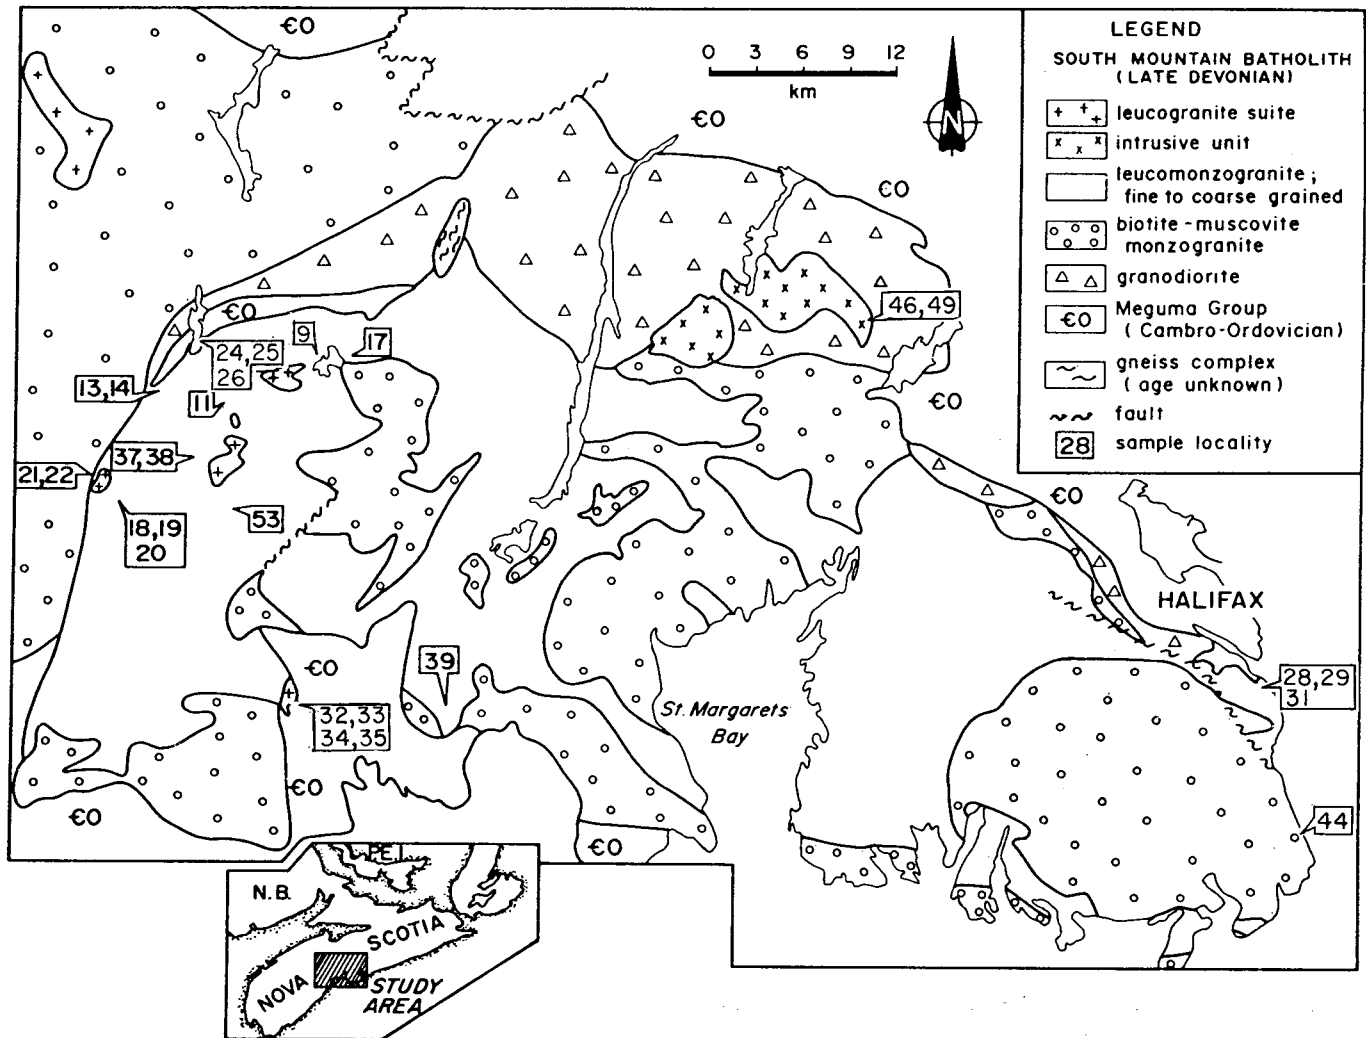

Fig. 1. Simplified geological map of the eastern part of the South Mountain Batholith (modified after MacDonald *et al.*, 1987) showing sample locations.

a whole-rock oxygen isotopic signature of 3.6 ‰ for an Elvan dyke rock at the Turner tin prospect was interpreted to indicate infiltration of an ^{18}O -depleted fluid at this locality, whereas involvement of an ^{18}O -enriched fluid was suggested by isotopic analyses of quartz from a greisen near Herring Cove.

In this paper, further geochemical and oxygen isotope data are presented for mineral phases (quartz, feldspar, muscovite, garnet, tourmaline) from pegmatites and greisens within the eastern part of the South Mountain Batholith (Fig. 1). We have concentrated our efforts in areas underlain by pegmatites and one well-developed greisen in order to more closely examine the isotopic and geochemical nature of fluids in the terminal stage of batholith evolution. Analyses of REE, compatible (Ba, Sr, Eu) and incompatible (Li, Cs, Rb) elements in feldspars and muscovites are employed to test for the relative roles of crystal fractionation and evolved fluids. The stable isotopic systematics of the principal mineralized centres (e.g., East Kemptonville) are the focus of other work (Kontak, 1988a) and, therefore, mineralization *sensu stricto* is not discussed herein. In addition to the isotopic and geochemical data, the degree of Al-Si order in alkali feldspar has been determined in order to provide further information on the thermal evolution of the areas examined.

GEOLOGICAL SETTING, SAMPLE LOCALITIES AND DESCRIPTIONS

The regional geological setting of the area of interest is discussed in detail by Kontak *et al.* (1988), MacDonald and Home (1988), MacDonald *et al.* (1987) and O'Reilly *et al.* (1982), to which the reader is referred for more detailed discussion of the geology. The sample localities (Fig. 1) remain the same as in our earlier study, but additional material has been analyzed from several localities (Table 1). A somewhat simplified classification of the material is provided in Table 1, with the site of interest described as granite (monzogranite, leucogranite), pegmatite or greisen. Both the samples reported on earlier (Kontak *et al.*, 1988) and the new material are listed in Table 1 in order to provide a complete data set for later discussion. Pertinent aspects of the material used in the present investigation are summarized below.

Whole-rock samples

A whole-rock granite sample (35) from Long Lake was analyzed. This is a fine-grained, muscovite-bearing leucogranite collected from drill core at the main mineralized showing. It is identical to sample 33 described in Kontak *et al.* (1988). The major- and trace-element (including REE) chemistry of this type-I leucogranite (see Kontak *et al.*, 1988) is provided in our previous publication. A quartz-feldspar mineral pair from the K-feldspar megacrystic biotite monzogranite (11-1) that hosts the Walker molybdenum showing also was analyzed.

Greisens

A single area of intense greisen development at Sandwich Point, just north of Herring Cove, is represented by samples 28

and 29. The area is fully described by MacDonald and O'Reilly (1989) and is of particular interest because of the presence of anomalous gold values in sulphide-bearing greisens. Sample 28, a muscovite-quartz±feldspar intergrowth, represents intense greisenization of the local two-mica monzogranite (represented by sample 29) in the form of a 1 m wide pod. Nearby, two samples of greisen veins were also collected. Sample 29A represents a replacement greisen in which the precursor monzogranite has been intensely altered owing to infiltration of fluids along a well developed system of fractures. The sample contains coarse (1-2 cm) clots of muscovite disseminated throughout the altered precursor. In contrast, sample 29B represents a vein infilling consisting of quartz-feldspar-muscovite±tourmaline±sulphides. This type of occurrence contains the anomalous gold values described by MacDonald and O'Reilly (1989).

Pegmatites

Several pegmatite localities are represented, most of these occurring in the vicinity of New Ross (Fig. 1). These localities are all very similar, with local pegmatitic segregations associated with fine- to medium-grained muscovite±biotite leucogranite. The following additional points are noted for some individual localities.

- (1) Walker molybdenum: 11 - banded aplite-pegmatite with finely disseminated molybdenite mineralization throughout.
- (2) Long Lake: 34B - coarse (cm-scale) quartz vein-segregation with abundant molybdenite flakes intergrown with milky white quartz. 32 - coarse (3-5 cm) K-feldspar grains grown on a fracture surface transecting greisenized leucogranite (see fig. 9 of O'Reilly *et al.*, 1982).
- (3) Morley's pegmatite: 36 - coarse (4-5 cm) rosettes of muscovite intergrown with quartz occur within feldspar-rich domains of the pegmatite. Muscovite rosettes probably postdated the feldspar.
- (4) Pockwock: 46-2 - this sample is itself not a pegmatite, but is included under this heading because of its association with pegmatites. The sample represents an occurrence of metasomatic garnet found in fine-grained aplitic dykes and two-mica monzogranite. The nature of the occurrence has been described in detail by Kontak and Corey (1988), in particular the sample from which the garnet was separated for oxygen isotopic analysis.

ANALYTICAL TECHNIQUES

Quartz, feldspar, garnet and tourmaline separates were prepared by first pulverizing samples to a coarse crush (<0.5-1 cm), followed by sieving and hand-picking. The high-grade concentrates were further comminuted (-20+40 mesh) and hand-picked under a binocular microscope to ensure high-quality concentrates. Mineral separates were subsequently cleaned using distilled water in an ultrasonic bath and then dried and stored in plastic vials. The feldspar fractions were crushed to -200 mesh using a steel shatter box in preparation for additional chemical analysis. Muscovite separates (-40+80 mesh) were prepared using conventional techniques of separation (i.e., magnetic separator and heavy liquids).

Note: except for samples 17-1, 17-2 the leucogranites occur as aplitic segregations within areas underlain by mixed pegmatite/leucogranite. Numbers in bold type represent analyses determined in this study. Abbreviations: wr - whole rock, qtz - quartz, kf - K-feldspar, alb - albite, ms - muscovite, gar - garnet, tour - tourmaline.

Major element analyses of feldspar concentrates were performed by G. Andrews at the Department of Earth Sciences, Memorial University, Newfoundland, employing wet-chemical digestion combined with Atomic Absorption Spectrometry. Trace element concentrations in feldspar and muscovite separates were obtained using the inductively coupled plasma mass spectrometry [ICP-MS; see Strong and Longerich (1985) for general discussion] facilities at Memorial University. Details of the procedures, analytical precision and accuracy are fully described by Longerich *et al.* (1990) and Jenner *et al.* (1990).

Oxygen isotopic compositions were determined on one whole-rock and 27 mineral separates at the University of Saskatchewan employing conventional procedures for the isotopic analysis of silicates (Clayton and Mayeda, 1963). Isotopic data are reported as $\delta^{18}\text{O}$ values in per mil (‰) relative to Standard Mean Ocean Water (SMOW) based on analysis of the NBS-28 laboratory standard. The overall reproducibility of $\delta^{18}\text{O}$ values is ± 0.18 ‰ (2 sigma).

X-ray powder diffractograms of pulverized K-feldspar separates were performed using an automated Philips X-ray powder

diffraction system at Memorial University, Newfoundland. Conditions employed in this study were $\text{CuK}\alpha$ radiation and a chart recorder speed of $1^\circ 2\theta/\text{minute}$. A more detailed analysis of the structural state of these samples, based on cell parameters, will be presented elsewhere.

ANALYTICAL RESULTS

Mineral chemistry

Muscovite separates from three pegmatites (11, 36, 49) and one greisen locality (28) were analyzed for their trace element contents (Table 2). Collectively the data show large variations in elements such as Li (209 to 955 ppm), Rb (848 to 4619 ppm), Zr (4.9 to 101 ppm), Cs (69 to 223 ppm) and Hf (0.7 to 15 ppm). Similarly, broad ranges are also observed for elemental ratios, for example Rb/Sr, Ba/Sr, U/Th and Zr/Hf (see Table 2). Such variations are typical for white micas within the South Mountain Batholith, based on previous studies (Ham and Kontak, 1988), although it is not always clear how much of the variation is

**Fig. 2.** Chondrite-normalized REE profiles for muscovite samples, South Mountain Batholith.

attributable to parameters such as different precursors in the case of greisens (e.g., granodiorite versus leucomonzogranite), crystal-chemical controls or presence of micro-inclusions. For example, the anomalous enrichment of Ba in greisen sample 28 is noted, as well as the elevated Zr and Hf contents in muscovite of pegmatite sample 36.

Chondrite-normalized REE plots for muscovite separates are shown in Figure 2. Sample 28 shows the largest absolute enrichment with an $(La/Lu)_N$ value of 30, a strongly fractionated pattern [$(La/Lu)_N = 13.4$] and a strong negative Eu anomaly ($Eu/Eu^* = 0.10$). This pattern is strikingly similar, both with respect to its shape and normalized values, to REE patterns obtained for muscovite from monzogranite (Ham and Kontak, 1988). In contrast, the three remaining muscovites from pegmatite occurrences are depleted in terms of absolute abundance with La_N values of about 0.3. In two samples (11, 49) the patterns are fractionated, with $(La/Lu)_N = 9.3$ and 3.4, respectively, but their Eu anomalies are variable, one being negative and the other positive ($Eu/Eu^* = 0.46$ and 11.0, respectively). In contrast, sample 36 shows an enrichment in the heavy REE, such that $(La/Lu)_N = 0.11$. This latter feature, in combination with elevated Zr and Hf contents of this sample (Table 2), suggests contamination by zircon inclusions (e.g., McLellan, 1989). In our earlier paper (Kontak *et al.*,

1988), we suggested that a similar pattern may have resulted from REE enrichment due to anionic complexes (e.g., F) in late-stage magmatic fluids. Clearly, the more complete set of analyses would favor enrichment due to incorporation of an accessory mineral such as zircon.

The major- and trace-element chemistries of 14 samples of K-feldspar and three of Na-feldspar are presented in Table 3. Based on nature of occurrence and bulk composition, the K-feldspar population can be subdivided into three groupings, namely: (1) granitic affinity (9, 29B, 31) with bulk composition $\sim Or_{60}$, (2) pegmatitic affinity (11, 18, 19, 22B, 22C, 24, 25B, 34A, 38, 49K) with bulk composition $\sim Or_{70-79}$, and (3) metasomatic affinity (32) with bulk composition Or_{93} . The second group can be further subdivided on the basis of covariation of Rb versus Sr. Samples 18, 19, 22B and 22C (group 2.2) are characterized by their elevated Rb/Sr values (Figs. 3, 4, Table 3). The K-feldspar populations examined in this study correspond to the broad groupings defined for the South Mountain Batholith based on the covariation of Ba and Sr versus Rb (Fig. 3; Kontak, 1988b; Kontak and Strong, 1988).

Chondrite-normalized REE plots for the K-feldspar separates are shown in Figure 5. Group 1 K-feldspar (Fig. 5A) is characterized by elevated absolute abundances compared to the other groups (Table 3, Fig. 4), strongly fractionated patterns [$(La/Yb)_N = 17.1-28.7$] and positive Eu anomalies ($Eu/Eu^* = 4.1-8.0$) for two of the samples. Sample 29B is noted for its lack of an Eu anomaly ($Eu/Eu^* = 0.94$). Group 2.1 K-feldspar has lower absolute abundances of REE (Figs. 4, 5B, 5C, Table 3) compared

Fig. 3. Sr and Ba versus Rb bivariate plots (contents in ppm) for alkali feldspars from the South Mountain Batholith. The fields labelled A, B, C and D are based on the variation of these elements in alkali feldspars from the appropriate rock units in the eastern part of the South Mountain Batholith [based on work of Kontak (1988b) and Kontak and Strong (1988)]. Note the break in the horizontal scale for Rb.

to group 1, is less fractionated [$(La/Yb)_N = 1.36-10.5$], and has either positive (34A, 49K) or negative (38, 11, 24, 25) Eu anomalies. Within group 2.1, there is a gradual decrease in absolute REE abundance that corresponds to increasing Rb/Sr values (Fig. 4), such that samples 34A and 49K are less fractionated (i.e., with respect to Rb/Sr values) compared to 24, 25B, 11 and 38.

Group 2.2 K-feldspar is characterized by still lower overall abundances of REE (Figs. 4, 5C), a less fractionated pattern [$0.34 < (La/Yb)_N < 1.71$], and probable negative Eu anomaly. The erratic nature of some of the profiles in Figure 5C is due in part to the low REE abundances (i.e., $< 0.2-0.3$ chondritic values), which approach limits of analytical detection. With respect to the REE contents, the single group 3 K-feldspar is similar to group 1 samples in terms of absolute abundances and its chondrite-

normalized pattern [$(La/Yb)_N = 5.9$ (Fig. 5B)], but differs by virtue of a negative Eu anomaly ($Eu/Eu^* = 0.6$).

The three albite separates analyzed have bulk compositions of Ab_{92-96} and trace element compositions comparable to the K-feldspar population, except for the notable depletion of Rb (Fig. 3). Chondrite-normalized REE patterns (Fig. 5D) indicate two distinct profiles. The profile for 49A is somewhat similar to the pattern for 49K K-feldspar because it is strongly fractionated [$(La/Yb)_N = 14.7$], whereas samples 36A and 36B have similar profiles, which show a reverse trend for La-Sm and large Eu anomalies ($Eu/Eu^* = 0.24, 0.39$) compared to 49A.

X-ray diffraction studies of the K-feldspar

X-ray powder diffractograms of K-feldspar separates analyzed

Fig. 4. Bivariate plot of Rb/Sr (log values) versus total REE contents of alkali feldspars, South Mountain Batholith. The significance of the groupings (1, 2.1, 2.2, 3) is discussed in the text.

in the present investigation are shown for the critical range of 2θ values between 29 and 31 degrees (Fig. 6). The majority of the samples correspond to monoclinic structures; by analogy to more detailed studies involving cell refinements (e.g., Cerny and Chapman, 1984), petrographic observations (i.e., 2V determinations) and unpublished cell refinements, these samples correspond to orthoclase or low sanidine. However, the presence of broad-shaped profiles for the $(131)_K$ reflection (cf. Jiranek, 1982) in some samples (11A, 17-2, 24, 31, 38) may indicate small but variable amounts of incipient development of triclinic domains. This is perhaps most evident in sample 38-1 which may contain a significant amount of intergrown triclinic K-feldspar. However, probably the most notable feature is the overall predominance of the monoclinic structural state for pegmatitic K-feldspars (e.g., note the sharp $(131)_K$ reflection for sample 22C) considering their formation in a fluid-rich environment (Parsons and Boyd, 1971; Parsons, 1977). In contrast to the aforementioned samples, development of triclinic phases occurs in samples 29B, 32 and 49, with the latter samples clearly reflecting the presence of both monoclinic and triclinic phases.

Oxygen isotope data

Results of oxygen isotopic determinations are presented in Table 1 and Figure 7. The single whole-rock analysis for sample 35, a muscovite-bearing leucogranite, of 11.0 ‰ is similar to results presented earlier, which averaged 10.6 ± 0.5 ‰ ($n=14$). Quartz separates show a broad range from 8.9 to 17.6 ‰ for the new determinations, comparable to the range reported earlier (8.9 to 18.2 ‰). Subdivision of the data into individual localities indicates no significant differences among the populations. A single determination on quartz from a monzogranite (11-1) gives 11.5 ‰, whereas two quartz samples from greisens have $\delta^{18}O$ values of 12.8 (29B) and 13.9 ‰ (29A), and pegmatitic quartz averages 12.4 ± 2.3 ‰ ($n=10$).

Eight new K-feldspar determinations are reported and, as with quartz, there are no apparent inter-occurrence variations. The two greisen-hosted samples (29A, B) have values of 15.1 and 8.1 ‰, respectively, whereas the granite-hosted samples (11-1, 14) have comparable values of 12.3 and 8.2 ‰. The four samples from pegmatitic occurrences define a smaller range with $\delta^{18}O$ of 10.9 ± 1.0 ‰. These results, like those for quartz, are broadly similar to the results reported earlier for the South Mountain Batholith. Two samples of albite from Morley's pegmatite have values (10.3 and 13.2 ‰) similar to K-feldspar.

Two new determinations have been made on muscovite, one from the greisen locality near Herring Cove (29A) and the other from Morley's pegmatite (36). The values of 10.8 and 9.3 ‰, respectively, are similar to three analyses (8.2, 8.8, 12 ‰) reported earlier (Kontak *et al.*, 1988). Finally, we report the results of single analyses of garnet (9.2 ‰) and tourmaline (10.4 ‰), which represent the first results on these mineral phases in the South Mountain Batholith.

DISCUSSION

The data presented above all have bearing, albeit in different ways, on aspects of the chemical and physical evolution of the South Mountain Batholith. For example, the trace element distributions in muscovite and feldspar are a function of crystal-chemical parameters during magmatic to late magmatic-pegmatitic stages, whereas the structures of the K-feldspar transcend this range and may also reflect physical conditions during the post-magmatic stage to temperatures below 400°C. The oxygen isotope data have the potential to reveal information from the early magmatic stage to the post-magmatic stage.

Implications of structural states of alkali feldspars

The series low sanidine-orthoclase-microcline is in part a reflection of decreasing thermal conditions; hence, the presence or absence of these polymorphs provides certain constraints on the thermal evolution of the host rocks, granites or otherwise. In detail, however, other factors, including composition of the mineral phase, bulk composition of the host rock and fluid phase, pressure (i.e., strain) and cooling rate, may also exert an influence on the ultimate structural state of alkali feldspar (see Martin, 1974; Parsons and Brown, 1984).

From the diffractograms presented above (also additional unpublished data of Kontak), it is obvious that the dominant K-feldspar polymorph is the monoclinic variety, that is low sanidine or orthoclase. This is found regardless of rock type (i.e., monzogranite versus pegmatite) and, therefore, the simple but generalized relationship of increasing ordering with increasing fluid pressure (e.g., Parsons and Boyd, 1971; Parsons, 1977; Parsons and Brown, 1984) does not appear to strictly apply here. A similar situation exists in other large granitoid batholiths, such as parts of the nearby St. George Batholith of southern New Brunswick (Cherry and Trembath, 1978) or the Wiborg rapakivi massif of southern Finland (Vorma, 1971). At the same time exceptions to this generalization exist, as illustrated by samples 29B, 32 and 49 (Fig. 6) where triclinic phases exist with or

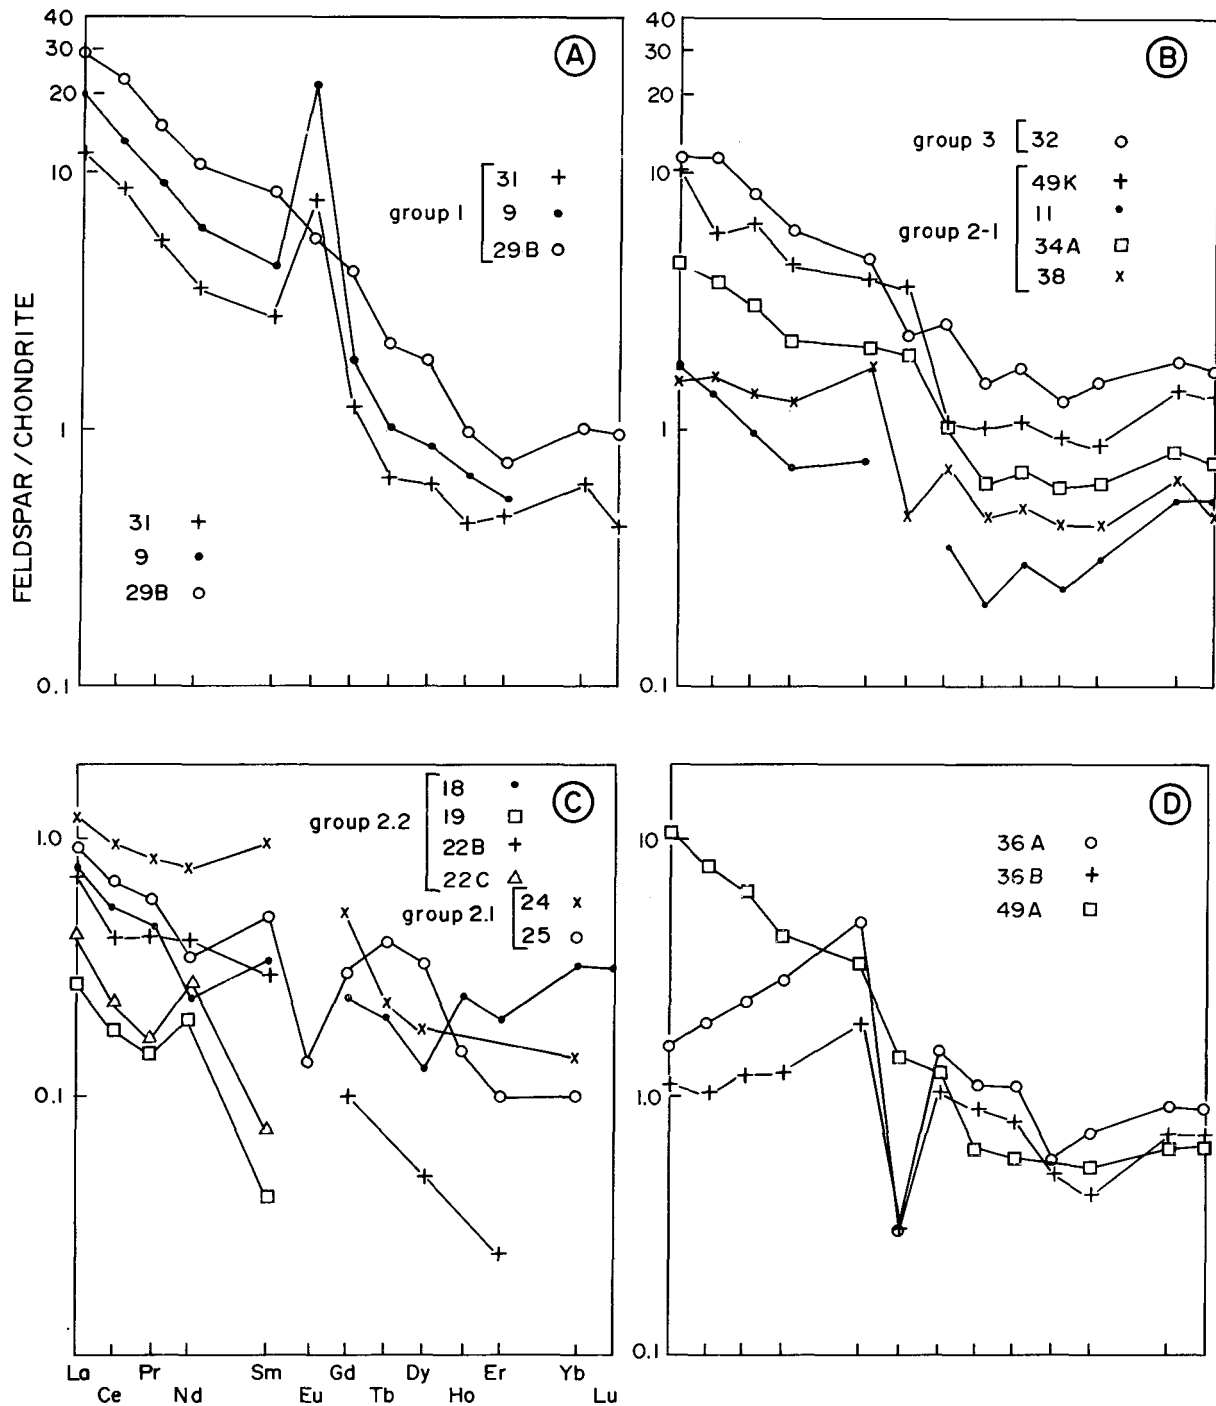

Fig. 5. Chondrite-normalized REE profiles for alkali feldspars, South Mountain Batholith (legend on lower left diagram applies to all the plots). The significance of the groupings (1, 2.1, 2.2, 3) is discussed in the text.

without monoclinic K-feldspar. We note here that in all three of these localities, fluids did play an important role in determining the observed phase assemblages. However, it is only in the case of sample 29B that apparently triclinic K-feldspar exists in isolation. The presence of grid twinning in this sample indicates that the feldspar inverted from a monoclinic structure during re-equilibration at a temperature of $<450^{\circ}\text{C}$ (Bambauer and Bernotat, 1982; Parsons and Brown, 1984).

The presence of at least two additional occurrences of triclinic

K-feldspar within the South Mountain Batholith indicates that its development is not as restricted as it might appear. The first example is from the Digby deep drillhole (see fig. 9 of Clarke and Chatterjee (1988) for details). Although the shallow parts of the hole contain fresh granodiorite, deeper intersections are albized and carbonized (i.e., episyenite) with concomitant reddening of the K-feldspar due to incipient hematitization (cf. Lalonde and Martin, 1983). Diffractograms of K-feldspar (Fig. 8A) from relatively pristine granodiorite (MRRD-1) through variably al-

Fig. 6. X-ray diffractograms for K-feldspars from the South Mountain Batholith. The labelled peaks refer to the important (hkl) reflections used to distinguish between monoclinic and triclinic K-feldspar. For example, sample 9 is an orthoclase, sample 29B is a microcline and samples 32 and 49 represent mixtures. See text for more detailed discussion.

tered to intensely altered granitoid rock (MRRD-10, 4, 11) show the progression in development of triclinic domains, with broadening of the $(131)_x$ reflection. Thus, based on the feldspar structure, it is concluded that hydrothermal activity related to alteration of the granodiorite occurred in part within the stability field of microcline (i.e., $\leq 450^\circ\text{C}$). The second example is from a pegmatite segregation within monzogranite near Herring Cove. At this locality, white K-feldspar is in part replaced by reddish K-feldspar (designated W and R, respectively, in Fig. 8) and the latter shows a marked broadening of the $(131)_x$ reflection compared to the fresh equivalent (Fig. 8B).

The presence of predominantly monoclinic K-feldspar within

the suite of K-feldspars examined is tentatively interpreted to reflect conditions, both physical and chemical, that collectively inhibited the development of triclinic K-feldspar. Thus, the overall peraluminous nature of the South Mountain Batholith (e.g., McKenzie and Clarke, 1975; MacDonald and Horne, 1988) may have been an important factor that retarded ordering, by analogy to previous studies that focused on experimental results (Martin, 1969) and natural occurrences (Guidotti, 1978; Guidotti *et al.*, 1973; Cerny and Chapman, 1984). Cooling rate also plays a role (e.g., Cherry and Trembath, 1978), although its significance is difficult to ascertain (Parsons and Brown, 1984). The latter authors argued that there is a minimum cooling rate that will retard the ordering process, but it is difficult to isolate this single factor from among several potentially contributing influences.

In the case of the South Mountain Batholith, the role of late-stage fluids is considered the most important factor in promoting ordering. In the areas where relatively highly ordered K-feldspar has been documented, there is clear independent evidence in terms of fluid inclusions, metasomatism and isotopic data that a late fluid phase has been present. In such areas an appropriate cooling rate must also have existed to facilitate the formation of microcline. In areas where similar fluid interaction occurred the thermal conditions may have been inappropriate for development of microcline or, alternatively, the temperature may have dropped too quickly and prevented ordering, since the monoclinic-triclinic inversion involves a kinetic barrier (Martin, 1974). Although the presence of disordered structural states of pegmatitic K-feldspar has in some cases been attributed to sudden escape of the volatile phase and, hence, stranding of a metastable structural phase (e.g., Martin and Falster, 1986), such a scenario is not considered realistic for the pegmatites of the South Mountain Batholith.

Implications of mineral chemistry for chemical evolution of the batholith

Muscovite

The four muscovite compositions reported herein all result from late-stage magmatic/hydrothermal processes and, as such, provide some information on the terminal stage in the evolution of the South Mountain Batholith. As noted above, sample 28 is chemically distinct from the others, and most of its chemistry is interpreted to reflect inheritance from the local monzogranite during greisenization (e.g., REE in Fig. 2). Chemical inheritance has also been noted in micas from greisen by Alderton *et al.* (1980), and in an earlier contribution Ham and Kontak (1988) presented evidence for similar behavior of greisen muscovite from the South Mountain Batholith. In fact, the REE pattern and trace element chemistry of this sample are quite similar to those of greisen muscovite from monzogranite presented by the latter authors (see Fig. 9 and below). In contrast, compositions of the remaining samples suggest products of relatively more evolved felsic melts. The REE patterns for samples 11 and 49 are the most depleted of any muscovite analyzed from the South Mountain Batholith, even more so than those from leucogranites (Ham and Kontak, 1988), and are notably less fractionated in terms of (La/

Fig. 7. Oxygen isotope values for mineral separates and whole-rocks from granites, pegmatites and greisens within the South Mountain Batholith (the samples are grouped according to locality; see Table 1 for sample locations). Note that the minerals (quartz, whole-rock, K-feldspar, albite and muscovite) are ordered in the manner they would appear if oxygen isotopic equilibrium was maintained. Note that for sample 22C quartz and K-feldspar overlap with identical values. The infilled symbols represent earlier data of Kontak *et al.* (1988).

Lu)_N. However, with respect to other trace elements (e.g., Li, Rb, Cs), these two muscovite separates are depleted, not enriched, relative to the muscovite from leucogranite (see Fig. 9). Also in Figure 9, the distinct chemistry of sample 28 is again noted and it is apparent that its signature is typical of a less evolved system.

There are different Eu anomalies in the REE patterns for samples 11 and 49. In one case (49) a positive anomaly is noted, whereas in the other (11) a negative Eu anomaly is present. Given the otherwise similar chemistries of these samples, these differences may reflect one or more of the following processes: (1) a change in fO_2 such that Eu^{2+} is relatively enriched in sample 11 compared to sample 49; (2) an Eu-bearing phase rich in Eu^{2+} , such as feldspar, may have been dissolved, thereby releasing Eu into the fluid phase, with subsequent incorporation into muscovite; and (3) a relatively more oxidizing fluid may have deposited muscovite at Walker molybdenum (11) such that Eu^{3+} was favored over Eu^{2+} .

K-Feldspar

The grouping of the major element chemistry of the K-feldspar samples, chiefly the K/Na ratios or mole-% Or (Table 3), is such that the compositional variation can be interpreted as reflecting different temperatures of crystallization from granitic melts \pm fluids (e.g., Parsons and Brown, 1984). Thus, the observed range in trace element chemistry of the K-feldspar from different

environments in part reflects this change in K/Na of the K-feldspar. It is, therefore, not surprising to find that the K-feldspar values collectively define a continuum in terms of chemistry, for example, the covariation of Ba and Sr versus Rb (Fig. 3), Rb/Sr versus REE (Fig. 4) and chondrite-normalized profiles (Fig. 5). This information is summarized in Figure 10 where all the K-feldspar data have been normalized to a K-feldspar sample from granodiorite (sample MRRD-1 in Fig. 8A). In this diagram there is a rotation of the data such that Li, Rb, Cs and Ga increase and Sr, Ba and La decrease with increasing fractionation. This continuum suggests that the medium from which the K-feldspar samples crystallized evolved in a systematic and progressive manner, precisely the conclusions arrived at on the basis of whole-rock chemistry (e.g., Clarke and Muecke, 1981; Kontak *et al.*, 1988; MacDonald and Horne, 1988).

Examination of the REE data in more detail shows that there is a marked change in the degree of fractionation from group 1 to group 2. This break is comparable to that observed between the REE patterns of monzogranite and leucogranite in the South Mountain Batholith (Kontak *et al.*, 1988; see also Clarke and Muecke, 1981). In the latter samples Kontak *et al.* (1988) argued that a fluid phase had been partly responsible for stripping the melts of light REE via chloride complexes (Flynn and Burnham, 1978). The chondrite-normalized REE profiles of K-feldspar hosted by pegmatites are similarly depleted in light REE, suggestive of a similar process.

Fig. 8. X-ray diffractograms of K-feldspars from the South Mountain Batholith. Note that Kf and Ab refer to reflections attributed to potassium- and sodium-bearing phases, respectively (i.e., orthoclase/microcline versus albite). (8A) Samples of K-feldspar showing progression from fresh granodiorite (MRRD-1) through variably altered granodiorite to the most intensely altered sample (MRRD-11). The dramatic increase in the Ab reflection ($20\bar{1}$) in sample MRRD-4 reflects albitization. (8B) Samples of K-feldspar from a pegmatite at Herring Cove. W and R refer to white and red, respectively; the color of the samples analyzed.

The gradual change in the Eu anomaly, from values $\gg 1$ to $\ll 1$, is sympathetic with variations in other chemical parameters. The decreasing abundance of Eu is consistent with feldspar fractionation and militates against the model of Fowler and Doig (1983) in which large negative Eu anomalies in evolved granites are related to hydrothermal alteration and subsequent liberation of Eu as Eu^{3+} . However, we note that the lack of a positive Eu

anomaly for sample 29B may indicate that late greisen-forming fluids at this locality were relatively oxidizing, given the presence of positive Eu anomalies in other cases of group 1 K-feldspar.

In contrast to other K-feldspar samples in the suite, the metasomatized sample (32) shows some elemental abundances more typical of a monzogranite than a pegmatitic affiliation (Figs. 4, 5,

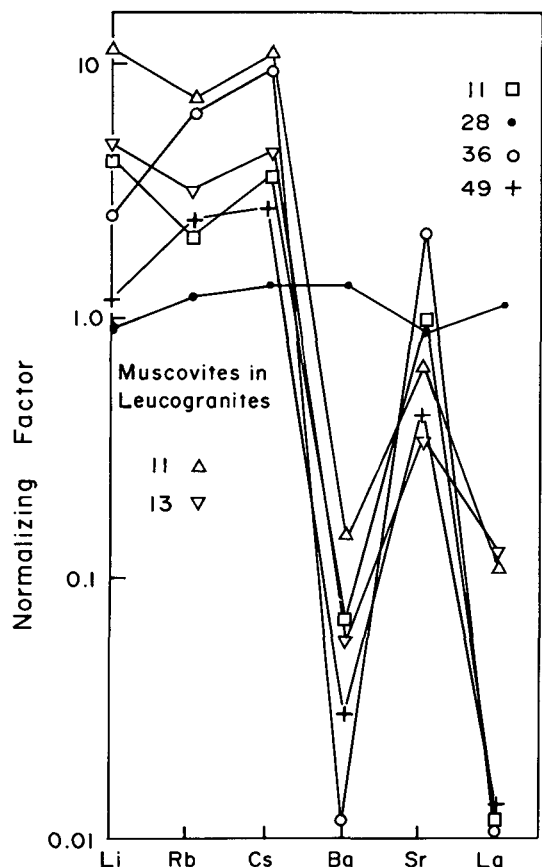

Fig. 9. Chemical data for muscovites from the South Mountain Batholith normalized to the chemistry of muscovite from a biotite-muscovite monzogranite (analysis 1 in Table 3 of Ham and Kontak, 1988). Also included for comparison are two muscovites from leucogranites (11, 13) as reported in Ham and Kontak (1988). Note the markedly different chemical profile for greisen sample 28 compared to the remaining samples from pegmatites.

10). This may suggest that the fluid from which this K-feldspar precipitated was derived from a less fractionated parental melt than that responsible for pegmatitic K-feldspar 34A.

The albite samples analyzed have comparable chemistries, except for the light REE which show divergent chondrite-normalized trends. This feature may reflect a relatively more evolved parental melt for samples 36A and 36B, compared to sample 49A, in light of the above discussion.

Implications of oxygen isotope data

The results of oxygen isotopic analyses have important implications with respect to (1) the source regions of melts, (2) equilibrium between mineral pairs and, hence, the degree of chemical equilibrium in the rock as a whole, and (3) interaction of the sample with a fluid phase and nature of the fluid reservoir (i.e., meteoric versus connate fluid). We have discussed the implications of the whole-rock data in terms of source regions elsewhere (Kontak *et al.*, 1988), as have Longstaffe *et al.* (1980), and the present data set indicates no reason to modify earlier interpretations. Thus, the reader is referred to these references for

a more detailed discussion.

The degree of equilibration of the mineral pairs can be assessed by examining the observed fractionation of ^{18}O between different minerals. The field for equilibrium fractionation of ^{18}O at high temperature (i.e., magmatic conditions) between quartz and K-feldspar is shown in Figure 11, with the available data from the South Mountain Batholith superimposed. The region for magmatic conditions within the South Mountain Batholith is defined using data for granodiorite and monzogranite reported by Longstaffe *et al.* (1980); it is apparent that these samples are in isotopic equilibrium, as they fall within the predicted range for magmatic conditions (i.e., $\Delta_{\text{quartz-feldspar}} = 0.5\text{--}2.0$). In addition, using the quartz-muscovite data of Longstaffe *et al.* (1980) and the appropriate fractionation factors, temperatures have been calculated (Table 4). The mean temperature of $599 \pm 65^\circ\text{C}$ ($n=3$) is sufficiently high to imply that mineral equilibria have been maintained in the granite samples. In contrast, quartz and feldspar samples in the present study, which come predominantly from pegmatites, scatter about the quartz-feldspar field of Longstaffe *et al.* (1980) such that the majority of quartz-feldspar fractionations are $>2.0\text{‰}$ or $<0.5\text{‰}$ and, hence, out of equilibrium. The dispersal of the data indicates exchange of the mineral(s) with relatively ^{18}O -enriched ($\Delta_{\text{quartz-feldspar}} < 0.5$) or -depleted ($\Delta_{\text{quartz-feldspar}} > 2$) fluids (Fig. 11). In addition, calculated temperatures for the pegmatite localities, based on quartz-muscovite pairs (Table 4), indicate a large range from 1042°C to 319°C . Whereas the former value is clearly too high for pegmatite formation, the three remaining temperatures (578, 506, 319) indicate that (1) mineral equilibrium has been variably retained, and (2) some constraining temperature limits for further calculations of $\delta^{18}\text{O}_{\text{fluid}}$ are established.

In order to evaluate the origin and role of fluids in the late-stage evolution of the batholith it is necessary to calculate the $\delta^{18}\text{O}_{\text{fluid}}$ assuming a realistic temperature, inferred from some independent line of evidence, and the appropriate mineral-water fractionation factor. In Figure 12 the ranges of $\delta^{18}\text{O}$ values determined for quartz, K-feldspar and muscovite are shown versus temperature with the $\delta^{18}\text{O}$ value of fluids in equilibrium with the minerals (as a function of $T^\circ\text{C}$ and $\delta^{18}\text{O}_{\text{mineral}}$) shown as a family of lines. Separate calculations have been made for muscovite (Table 4), albite (Table 5) and garnet (see below). The temperature range used in the calculations is ca. $350\text{--}500^\circ\text{C}$ based on the following: (1) the temperature of formation of pegmatites in general and experimental work on granite systems (e.g., Tuttle and Bowen, 1958); (2) calculated temperatures based on $\delta^{18}\text{O}$ fractionation between quartz and muscovite (see above); (3) the presence of predominantly monoclinic K-feldspar in the pegmatites, i.e., $T > 450^\circ\text{C}$; and (4) the temperature range in which exchange is likely to occur based on previous studies (see Taylor, 1978, 1988). Errors in estimated temperature at the high end of the scale result in minimal changes in calculated $\delta^{18}\text{O}_{\text{fluid}}$ (see Fig. 12) since mineral-water isotopic fractionations decrease systematically at elevated temperatures, and there is little evidence in any of the areas examined for significant fluid interaction over a protracted time period at temperatures lower than those indicated in Figure 12. This latter point is supported by the absence of the appropriate alteration assemblages (e.g., clay alteration) and the lack of an

Fig. 10. Chemical data for K-feldspars from the South Mountain Batholith normalized to the chemistry of a K-feldspar (MRRD-1; unpublished data of Kontak) from a granodiorite in the Digby deep drillhole. Note that the data for Sr and Ba are multiplied by 10 for convenience of plotting.

extended array of data in Figure 11 (cf. Taylor, 1988).

Quartz separates collectively show a broad range in $\delta^{18}\text{O}$ values and, accordingly, indicate a spectrum in $\delta^{18}\text{O}_{\text{fluid}}$ of 16.4 ‰, using maximum variation in temperature constraints and $\delta^{18}\text{O}_{\text{quartz}}$. However, of the 22 analyses in total, 16 fall in a narrower range corresponding to $\delta^{18}\text{O}_{\text{fluid}}$ of 10.5–6 ‰; hence, the excursions to enriched and depleted fluid values are atypical. Magmatic fluids evolved from normal ^{18}O granitoids ($6 < \delta^{18}\text{O} < 9$) are generally considered to have $\delta^{18}\text{O}$ values of 6 to 8 ‰, whereas high ^{18}O granitoids may have more enriched fluids. In detail we note that at single localities there may exist a large variation in the inferred $\delta^{18}\text{O}_{\text{fluid}}$. For example, at Herring Cove a spread in $\delta^{18}\text{O}_{\text{quartz}}$ of 5.4 ‰ would translate into an equivalent spread for $\delta^{18}\text{O}_{\text{fluid}}$ (i.e., 11–6 ‰). Such a range is larger than can be explained by the inferred temperature range (500–350°C corresponds to 3 ‰ change) and suggests a mixing of fluids. A similar situation exists at the Keddy's and Reeves localities (Fig. 1 and Table 1), where the maximum variations in $\delta^{18}\text{O}_{\text{quartz}}$ are 5.7 and 4.1, respectively. Smaller variations occur at the other localities, namely Pockwock (0.7 ‰), Morley's (2.0 ‰), Long Lake (2.2 ‰), Grassy Brook (1.1 ‰) and Walker molybdenum (3.6 ‰).

K-feldspar separates collectively show a spread in $\delta^{18}\text{O}$ of 8.2

to 15.1 ‰ and indicate a range in $\delta^{18}\text{O}_{\text{fluid}}$ of 14.4 ‰, a value closely approximating that indicated by quartz. As with quartz, the sample with the most enriched $\delta^{18}\text{O}$ value is from the greisen at Herring Cove. Detailed examination of the individual localities again indicates that differences occur for multiple analyses of K-feldspar from individual localities. The largest difference is found at Herring Cove (7.0 ‰), with much smaller variations at Keddy's (0.4 ‰), Reeves (1.7 ‰) and Grassy Brook (1.2 ‰). At Pockwock and Long Lake, identical values were obtained on separate K-feldspar samples. Multiple analyses of quartz from these same two localities also gave very similar results.

Muscovite separates define a narrow range in terms of $\delta^{18}\text{O}$ from 8.2 to 12.0 ‰ which translates into a correspondingly small range for $\delta^{18}\text{O}_{\text{fluid}}$ of ca. 6.5 to 12 ‰. The $\delta^{18}\text{O}_{\text{fluid}}$ values are presented in Table 4 using the temperatures derived from quartz-muscovite fractionations; they define a more restricted range from 9.1 to 10.7 ‰, depending on the fractionation factor used (see Table 4). Values of $\delta^{18}\text{O}_{\text{fluid}}$ based on the muscovite data of Longstaffe *et al.* (1980; Table 4) define a comparable range (8–12 ‰) to that calculated above.

The results of calculations for fluids in equilibrium with the two albite samples from Morley's pegmatite indicate values spanning a broad range from 4 to 12 ‰, depending again on the

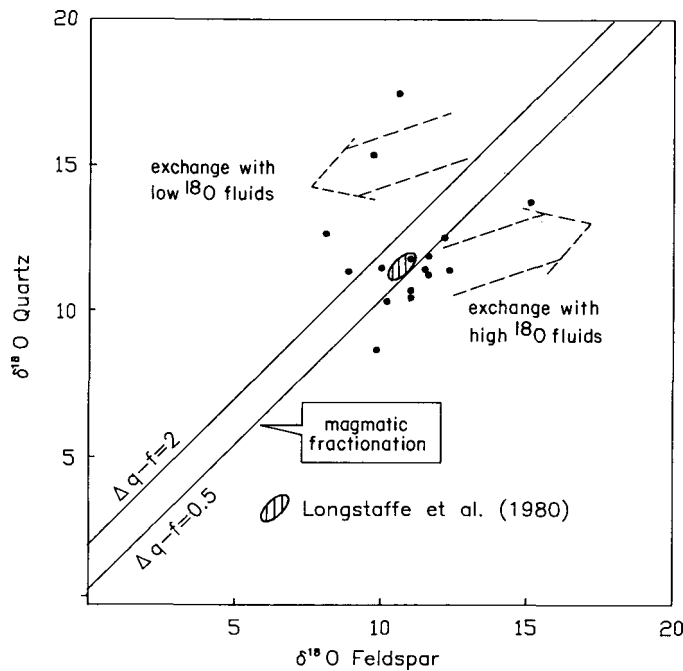

Fig. 11. Bivariate plot of oxygen isotopic data for coexisting quartz and K-feldspar in granites and pegmatites of the South Mountain Batholith. The trend for magmatic fractionation is inferred from the equilibrium fractionation of ^{18}O between quartz and feldspar at elevated temperatures. Field for granites (vertical lines) is defined using the data ($n=6$) of Longstaffe *et al.* (1980). Note that most of the samples from pegmatite localities fall outside the field for magmatic fractionation and indicate disequilibrium conditions due to exchange of either one or both of the minerals with ^{18}O -enriched (heavy) or -depleted (light) fluids.

fractionation factor used. These values fall within the range indicated by K-feldspar (see above). Again, the differences observed are unlikely to be related simply to a change in temperature of equilibration of the two feldspar samples.

The single garnet analysis reported equates to a $\delta^{18}\text{O}_{\text{fluid}}$ value (using the fractionation factor of Bottinga and Javoy, 1975) of between 10.2 (400°C) and 11.2 ‰ (600°C), depending upon the temperature used. From the detailed studies of Corey (1988) the higher temperature limit is probably more reasonable given the alteration assemblage present in the area.

The fractionation factor for tourmaline- H_2O has not been experimentally determined and, therefore, a $\delta^{18}\text{O}_{\text{fluid}}$ value cannot be independently derived. However, from empirical observation the $\delta^{18}\text{O}$ of tourmaline is approximated by $\delta^{18}\text{O}$ of K-feldspar minus 0.5 ‰ (B.E. Taylor in Beaty *et al.*, 1988) and the fractionation of $\delta^{18}\text{O}$ between quartz and tourmaline from granitic pegmatites indicates that quartz is enriched by 2.0 ‰ (Taylor and Slack, 1984). If these assumptions are correct, then the quartz and tourmaline in sample 44B are in isotopic equilibrium ($\Delta = 2.2$ ‰), whereas the feldspar and tourmaline are not ($\Delta = 1.8$ ‰). The absolute $\delta^{18}\text{O}$ value of 10.4 ‰ for the tourmaline is slightly greater than the range (6-10.2 ‰) for pegmatitic tourmaline compiled in Taylor and Slack (1984).

From the foregoing discussion it is apparent that whereas whole-rock $\delta^{18}\text{O}$ values are relatively constant and define a small range (10.6 ± 0.5 ‰; Table 1 and Fig. 7), the $\delta^{18}\text{O}_{\text{mineral}}$ values are

Temperatures calculated using the quartz-muscovite mineral fractionation equation of Bottinga and Javoy (1975). O&T refers to O'Neil and Taylor (1969) and B&J refers to Bottinga and Javoy (1973). Note that for samples 11 and 36 fluid compositions are not calculated because of unrealistic temperature and fractionation values, respectively.

much more scattered. The mineral separates analyzed by Longstaffe *et al.* (1980; plotted in Fig. 11) indicate equilibrium on a whole-rock scale; in contrast the data for pegmatites generally reflect disequilibrium conditions. There is evidence from structural studies of the K-feldspar analyzed that fluid-rock interaction persisted below 450°C to produce triclinic domains. Fractionation of ^{18}O between quartz and muscovite corroborates this (Table 4). Thus, the oxygen isotope data indicate that in the late-stage evolution of the batholith, fluid-rock interaction resulted in disequilibria among coexisting silicate phases with respect to ^{18}O in which feldspar and muscovite undergo preferential re-equilibration. Given the restricted range in $\delta^{18}\text{O}_{\text{whole-rock}}$ and the temperature range over which fluid interaction occurred, it appears necessary to involve additional fluids to account for the large variations in $\delta^{18}\text{O}_{\text{fluid}}$ documented above.

Nature of fluids in the late-stage evolution of the batholith

The range of $\delta^{18}\text{O}_{\text{fluid}}$ of magmatic provenance is generally between +5.5 and +10.0 ‰, excluding exceptional circumstances, whereas the range of $\delta^{18}\text{O}_{\text{fluid}}$ derived from metamorphic rocks is generally +5 to +25 ‰ (Taylor, 1979). Given that the whole-rock oxygen isotope data for the batholith fall near the spectrum for normal igneous rocks, we feel justified in concluding that fluids derived from these granitoid rocks should correspond to the spectrum for magmatic fluids. Most of the fluid compositions inferred above fall in the range of 5-10 ‰, or slightly greater, therefore indicating that a magmatic derivation is appropriate. However, excursions from the magmatic field are indicated by several samples which suggest that infiltration occurred by both $\delta^{18}\text{O}$ -enriched and -depleted fluids. The light $\delta^{18}\text{O}$ signatures are indicated by single quartz values from Walker molybdenum (8.9 ‰) and Morley's pegmatite (8.9 ‰), K-

Fig. 12. Plots of temperature ($^{\circ}\text{C}$) versus oxygen isotopic composition of quartz, K-feldspar and muscovite as given in Table 1. The temperature range of ca. 500-350 $^{\circ}\text{C}$ outlined by the boxes is discussed in the text. The family of lines in the diagrams represent the $^{18}\text{O}_{\text{fluid}}$ in equilibrium with the minerals at defined values of $^{18}\text{O}_{\text{mineral}}$ and temperature. The vertical lines indicate the range for magmatic fluids derived from normal granites. Figures have been designed using the appropriate mineral- H_2O fractionation factors for quartz (Clayton *et al.*, 1972), K-feldspar (O'Neil and Taylor, 1967) and muscovite (Bottinga and Javoy, 1973).

Table 5. Calculated $^{18}\text{O}_{\text{fluid}}$ in equilibrium with albite for different temperatures.

Temperature	#36A	#36B
500 $^{\circ}\text{C}$	11.7/11.6	8.8/8.7
400 $^{\circ}\text{C}$	10.4/10.0	7.5/7.1
300 $^{\circ}\text{C}$	7.4/7.3	5.5/4.4

Note that the higher values for each temperature were calculated using the albite- H_2O equilibria of Matsuhisa *et al.* (1979) while the lower values were obtained using the equation of Bottinga and Javoy (1973).

feldspar values from Turner tin (8.2 ‰), Herring Cove greisen (8.1 ‰) and Grassy Brook (8.9 ‰), and a single whole-rock value from Turner tin (3.6 ‰) (see Fig. 12 to compute the equivalent $\delta^{18}\text{O}_{\text{fluid}}$ value).

The presence of ^{18}O -enriched fluids is indicated for two pegmatite localities (Reeves, Keddy's) and the greisen at Herring Cove. The explanation favoured for the origin of these fluids involves derivation of an ^{18}O -enriched fluid from the Meguma Group. However, additional evidence for more widespread infiltration of metamorphic fluids is found in the overall range of the data for the mineral separates and, therefore, similarly large spread of $\delta^{18}\text{O}_{\text{fluid}}$ that would be in equilibrium with these phases. As noted earlier, the inferred range of temperature used in Figure 12 is not large enough to generate the observed differences in fluid compositions. The restricted range in whole-rock $\delta^{18}\text{O}$ values indicates that fluid interaction with this medium cannot account for the spread. However, variable degrees of infiltration and fluid/rock equilibration by both ^{18}O -enriched and -depleted fluids could account for the observed variations. Interaction with an externally derived fluid also would account for the disposition of points in Figure 11, which indicates that both quartz and K-feldspar have exchanged with such fluids.

The local variation in the $\delta^{18}\text{O}$ composition of mineral phases within single pegmatite localities (e.g., Keddy's, Reeves) or the greisen at Herring Cove indicates heterogeneity on a very small scale with respect to the isotopic composition of the fluid. Several workers (London, 1986; Morgan and London, 1987; Thomas and Spooner, 1988; Thomas *et al.*, 1990) have documented the involvement of different fluids in the border zone of the Tanco pegmatite. The mixing of fluids of distal origins is well documented in the formation of, for example, skarn W (e.g., Bowman *et al.*, 1985; Brown *et al.*, 1985; Gerstner *et al.*, 1989) and porphyry Cu (Reynolds and Beane, 1985) deposits. Thus, the documentation of apparently extraneous fluids in the late-stage evolution of the batholith is not without parallel.

CONCLUSIONS

This study of the physical and chemical evolution of the eastern part of the South Mountain Batholith supports the following conclusions:

(1) Mineral compositions of K-feldspar, albite and muscovite corroborate earlier geochemical investigations based on both whole-rock and mineral chemistry. The mineral chemistries of

analyzed phases define a continuum with respect to the magmatic evolution of the batholith. In the more primitive magmatic stage of the batholith, crystal fractionation of the major silicate phases lead to depletion of elements such as Ba, Sr and Σ REE with enrichment of Li, Cs and Rb (e.g., Fig. 10). The influence of a fluid phase during the late-stage evolution of the batholith is indicated by the shape of light REE profiles in chondrite-normalized plots of the K-feldspar, therefore corroborating similar conclusions based on whole-rock studies (Clarke and Muecke, 1981; Kontak *et al.*, 1988).

(2) Where greisen zones are developed, chemical inheritance occurs such that the precursor rock plays a dominant role in determining the chemistry of alteration phases (e.g., muscovite at Herring Cove).

(3) The gradual decrease in Eu/Eu* values for K-feldspar suggests that observed Eu anomalies in this mineral reflect feldspar fractionation within the melt and are not the result of metasomatic processes (cf. Fowler and Doig, 1983).

(4) Oxygen isotopic data for quartz, feldspars and muscovite confirm earlier conclusions based on a more limited database. Whereas isotopic equilibrium was established and maintained among mineral phases from granodiorites and monzogranites, widespread disequilibrium is present among the mineral phases sampled in pegmatite and a greisen, signifying preferential late-stage re-equilibration of feldspar and muscovite.

(5) Calculated values of $\delta^{18}\text{O}_{\text{fluid}}$ indicate that whereas most of the compositions fall in or near the magmatic range, deviations to higher (to +18 ‰) and lower (+4 ‰) values occur. This information, in conjunction with larger than expected spreads in isotopic data for single mineral phases in the temperature range considered (500-350°C) at the same localities, suggests that exotic fluids (i.e., with respect to local igneous environment) infiltrated these areas.

(6) Structural determinations of the K-feldspar separates used in the geochemical and isotopic studies indicate that monoclinic structures dominate. However, triclinic feldspar does occur in areas where observations suggest extreme fluid/rock interaction (e.g., alteration zones). The general absence of highly ordered feldspars in pegmatitic environments probably reflects a rapid cooling rate owing to sudden uplift (?) such that the poorly ordered K-feldspar remains as a stranded metastable phase.

ACKNOWLEDGEMENTS

This research was funded through NSERC grants to D.F. Strong and R. Kerrich. D.J. Kontak acknowledges financial support in the form of a post-doctoral fellowship through funds from D.F. Strong (NSERC Grant No. A7975). The stable isotope laboratory at the University of Saskatchewan is supported by an NSERC Infrastructure Grant. Part of this research was also funded by the Nova Scotia Department of Mines and Energy through the Canada - Nova Scotia Mineral Development Agreement (1984-1989). D.J. Kontak especially thanks the South Mountain Batholith crew for providing accommodation and field support during the 1985 field season. The major element chemistry was capably done by G. Andrews, and the trace elements by Drs. H. Longrich and S. Jackson, all at Memorial University, St.

John's, Newfoundland. Nova Scotia Department of Mines and Energy personnel are thanked for their help in preparing the figures and text.
